Layer-by-layer stacking or lateral interfacing of atomic monolayers has opened up unprecedented opportunities to engineer two-dimensional heteromaterials. Fabrication of such artificial heterostructures with atomically clean and sharp interfaces, however, is challenging. Here, we report a one-step growth strategy for the creation of high-quality vertically stacked as well as in-plane interconnected heterostructures of WS$_2$/MoS$_2$ via control of the growth temperature. Vertically stacked bilayers with WS$_2$ epitaxially grown on top of the MoS$_2$ monolayer are formed with preferred stacking order at high temperature. A strong interlayer excitonic transition is observed due to the type II band alignment and to the clean interface of these bilayers. Vapour growth at low temperature, on the other hand, leads to lateral epitaxy of WS$_2$ on MoS$_2$ edges, creating seamless and atomically sharp in-plane heterostructures that generate strong localized photoluminescence enhancement and intrinsic p–n junctions. The fabrication of heterostructures from monolayers, using simple and scalable growth, paves the way for the creation of unprecedented two-dimensional materials with exciting properties.

Heterostructures have been the essential elements in modern semiconductor industry, and play a crucial role in high-speed electronics and optoelectronic devices[1,2]. Beyond conventional semiconductors, two-dimensional (2D) materials provide a wide range of basic building blocks with distinct optical and electrical properties, including graphene[3], hexagonal boron nitride[4,5] and transition-metal dichalcogenides (TMDs; refs 6–9). These atomic monolayers could also be combined to create van der Waals heterostructures, where monolayers of multiple 2D materials are stacked vertically layer-by-layer, or stitched together seamlessly in-plane to form lateral heterojunctions. Many physical properties have been explored on such van der Waals heterostructures, and devices with improved performance have been demonstrated[10–14]. The lateral heterojunctions could also lead to exciting new physics and applications. For example, the semiconducting monolayer TMDs can serve as building blocks for p–n junctions and other optoelectronic devices[15–17]. However, the fabrication of 2D heterostructures with clean and sharp interfaces, essential for preserving optoelectronic properties driven by the interlayer or intralayer coupling, remains challenging. Van der Waals heterostructures could be created by stacking different 2D materials using mechanical transfer techniques[12]. However, the stacking orientation cannot be precisely controlled, the interface between layers can be easily contaminated[18,19], and there are

significant challenges for massive production of the samples. Lateral heterostructures, in contrast, can be created only via growth. Both vertical and in-plane heterostructures of semi-metallic graphene and insulating hexagonal boron nitride have recently been demonstrated via chemical vapour deposition (CVD; refs 20–24); however, direct growth of heterostructures consisting of different semiconducting monolayers has not been achieved.

Here, we report a scalable single-step vapour phase growth process for the creation of highly crystalline vertical stacked bilayers and in-plane interconnected WS$_2$/MoS$_2$ heterostructures, respectively, under different growth temperatures. Atomic-resolution scanning transmission electron microscopy (STEM) imaging reveals that high-temperature growth yields predominantly vertically stacked bilayers with WS$_2$ epitaxially grown on top of the MoS$_2$ monolayer, following the preferred 2H stacking. In contrast, low-temperature growth creates mostly lateral heterostructures of WS$_2$ and MoS$_2$ within a single hexagonal monolayer lattice, with atomically sharp heterojunctions along both the zigzag and armchair directions. The vertical and lateral heterostructures are further verified by Raman and photoluminescence (PL) spectroscopy characterization. Strong interlayer or intralayer excitonic interactions between MoS$_2$ and WS$_2$ are observed by PL spectroscopy for the first time on these two types of heterostructures, owing to their clean and sharp interfaces.

SEM images are presented in reverse contrast. The green, purple and yellow spheres in **a,e** represent W, Mo and S atoms, respectively. **i**, Schematic of the synthesis process for both heterostructures.

Specifically, a bandgap of 1.42 eV is observed in the bilayer heterostructure, arising from the interlayer excitonic transition between MoS$_2$ and WS$_2$ (refs 25,26); whereas a strong localized PL enhancement is observed at the lateral interface between MoS$_2$ and WS$_2$, presumably due to the increased excitonic recombination of the as-generated electron–hole pairs at the atomically sharp interface[27]. These two types of heterostructures are further demonstrated to be building blocks for high-mobility field-effect transistors (FET) and planar monolayer p–n junctions, indicating their potential for constructing unique devices.

Synthesis and morphology

Figure 1i shows the scheme for the growth of WS$_2$/MoS$_2$ heterostructures. Molybdenum trioxide (MoO$_3$) powder is placed in front of the bare SiO$_2$/Si wafer for the growth of MoS$_2$, while a mixed powder of tungsten and tellurium is scattered on the wafer for the growth of WS$_2$. The addition of tellurium helps to accelerate the melting of tungsten powder during the growth (Supplementary Fig. 4). Sulphur powder is put upstream within the low-temperature zone. Argon is used to protect the system from oxygen and carry sulphur vapour from the upstream of the tube during the reaction. The difference in their nucleation and growth rates gives rise to sequential growth of MoS$_2$ and WS$_2$, instead of Mo$_x$W$_{1-x}$S$_2$ alloy, and the precise reaction temperature determines the structure of the final product: vertically stacked bilayers are preferred at ~850 °C, whereas in-plane lateral heterojunctions dominate when the synthesis is carried out at ~650 °C (see Supplementary Information for more details). A brief discussion of the possible mechanism of the temperature-selective growth is provided in the Supplementary Information. This simple, scalable growth process creates clean interfaces between the two monolayer components, which is advantageous over mechanical transfer of layers.

The morphology of the WS$_2$/MoS$_2$ vertical and in-plane heterostructures was examined by optical microscopy, scanning electron microscopy (SEM) and atomic force microscopy (AFM). Figure 1a–d are the schematic and typical optical and SEM images of the vertically stacked heterostructures, showing individual WS$_2$/MoS$_2$ bilayer triangles and a high yield of heterostructures. The bilayers can be easily distinguished from monolayers via optical contrast (Fig. 1b), with MoS$_2$ monolayers showing a light purple colour and the bilayer regions as much darker purple. The domain size of the bottom MoS$_2$ layer is typically larger than 10 μm. Both totally covered and partially covered WS$_2$/MoS$_2$ bilayers (Supplementary Fig. 5) can be found, providing different geometries for device fabrication. The schematics and morphology of WS$_2$/MoS$_2$ in-plane heterostructures are shown in Fig. 1e–h, where the lateral interface between monolayer MoS$_2$ and WS$_2$ can be easily distinguished by the contrast difference. Optical and SEM images shown in Supplementary Fig. 6 demonstrate the high yield of such in-plane heterostructures obtained from this growth method. The difference in bilayer or monolayer morphology of these two types of heterostructures is further verified by AFM images presented in Supplementary Fig. 7.

Vertically stacked bilayer heterostructures

The atomic structure of the vertically stacked WS$_2$/MoS$_2$ bilayers was studied by Z-contrast imaging and elemental mapping on an aberration-corrected STEM (see Supplementary Information). Figure 2a shows the morphology of the as-transferred stacked WS$_2$/MoS$_2$ heterostructure in a low-magnification Z-contrast image, where the image intensity is directly related to the averaged atomic number and the thickness of the sample[28–30]. A WS$_2$ monolayer would, therefore, exhibit higher image contrast than a MoS$_2$ monolayer, whereas the image intensity from the bilayer heterostructure is roughly the sum of that from its two monolayer components. To highlight the different regions in the sample, the image in Fig. 2a is shown with a false colour scale. Most of the sample is covered by a continuous bilayer heterostructure (orange
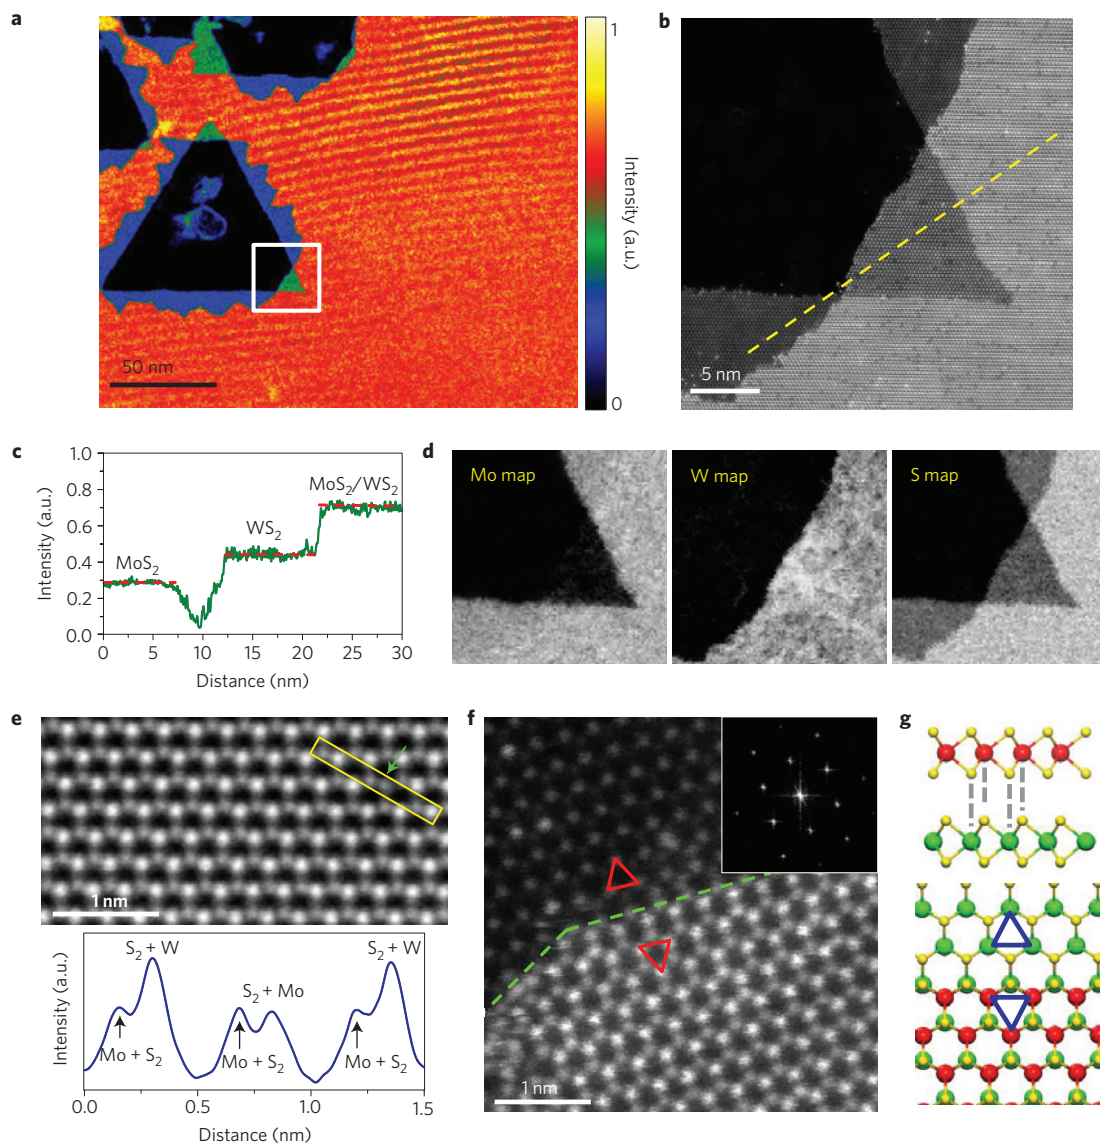

Figure 2 | STEM Z-contrast imaging and elemental mapping of the stacked WS$_2$/MoS$_2$ heterostructures. a, Low-magnification false-colour Z-contrast image of the sample, where monolayer MoS$_2$ is shown in blue, monolayer WS$_2$ in green, and the WS$_2$/MoS$_2$ bilayer in orange. **b**, Zoom-in view of the region outlined by the square in **a**. **c**, Z-contrast image intensity profile along the dashed line in **b**, showing the distinct contrast variation among the different monolayer and bilayer regions. **d**, Elemental mapping of Mo, W and S from the whole area shown in **b**. **e**, Top: Z-contrast image of the bilayer region with a 2H stacking orientation. The brighter columns are overlapping columns of W and S$_2$, whereas the less bright columns are overlapping of S$_2$ and Mo. The green arrow points to the atomic positions where a W atom is replaced by a Mo atom in the WS$_2$ layer, which has a similar intensity to its neighbouring site. Bottom: Image intensity profile acquired along the yellow rectangle in the image above. **f**, Z-contrast image of the step edge of the WS$_2$/MoS$_2$ bilayer. The green dashed line indicates the step edge, and the two triangles indicate the orientation of the MoS$_2$ (top part of image) and WS$_2$ (bottom part) layers. Inset: Fast Fourier transform of the Z-contrast image showing only one set of diffraction patterns. **g**, Schematic of the 2H stacking in the stacked WS$_2$/MoS$_2$ heterostructure.

region), while at some intentionally induced broken edges (see Supplementary Information) both of the individual monolayers can be identified (with MoS$_2$ shown in blue and WS$_2$ shown in green). Figure 2b shows a magnified image of the region outlined by a square in Fig. 2a. The obvious contrast step across the two individual layers, as shown by the image intensity line profile in Fig. 2c, demonstrates the presence of separated MoS$_2$ and WS$_2$ monolayers instead of a homogeneous Mo$_x$W$_{1-x}$S$_2$ alloy. Elemental mapping of Mo, W and S (Fig. 2d and Supplementary Fig. 8) from the same region unambiguously confirms that MoS$_2$ and WS$_2$ are well separated into two atomic layers, forming vertical bilayer heterostructures.

Figure 2e,f shows atomic-resolution Z-contrast images from the bilayer region and a step edge of the WS$_2$/MoS$_2$ heterostructure,

respectively. The alternative bright and dark atomic column arrangement in the hexagonal lattice suggests the as-grown stacked WS$_2$/MoS$_2$ heterostructure preserves the 2H stacking, where the bright and dark columns are W and Mo atom-aligned with a S$_2$ column, respectively, as illustrated in Fig. 2g. The WS$_2$/MoS$_2$ heterostructure grown by our one-step growth method is found to have predominantly the 2H stacking, which exemplifies the advantage of this direct growth method over the mechanical transfer method, where the stacking orientation of the heterostructure cannot be well controlled. As a side note, Mo substitution in the WS$_2$ layer can occasionally be observed, as indicated by the reduced contrast at the W atomic sites (green arrows in Fig. 2e and the associated intensity line profile). Similarly, some trace amount of
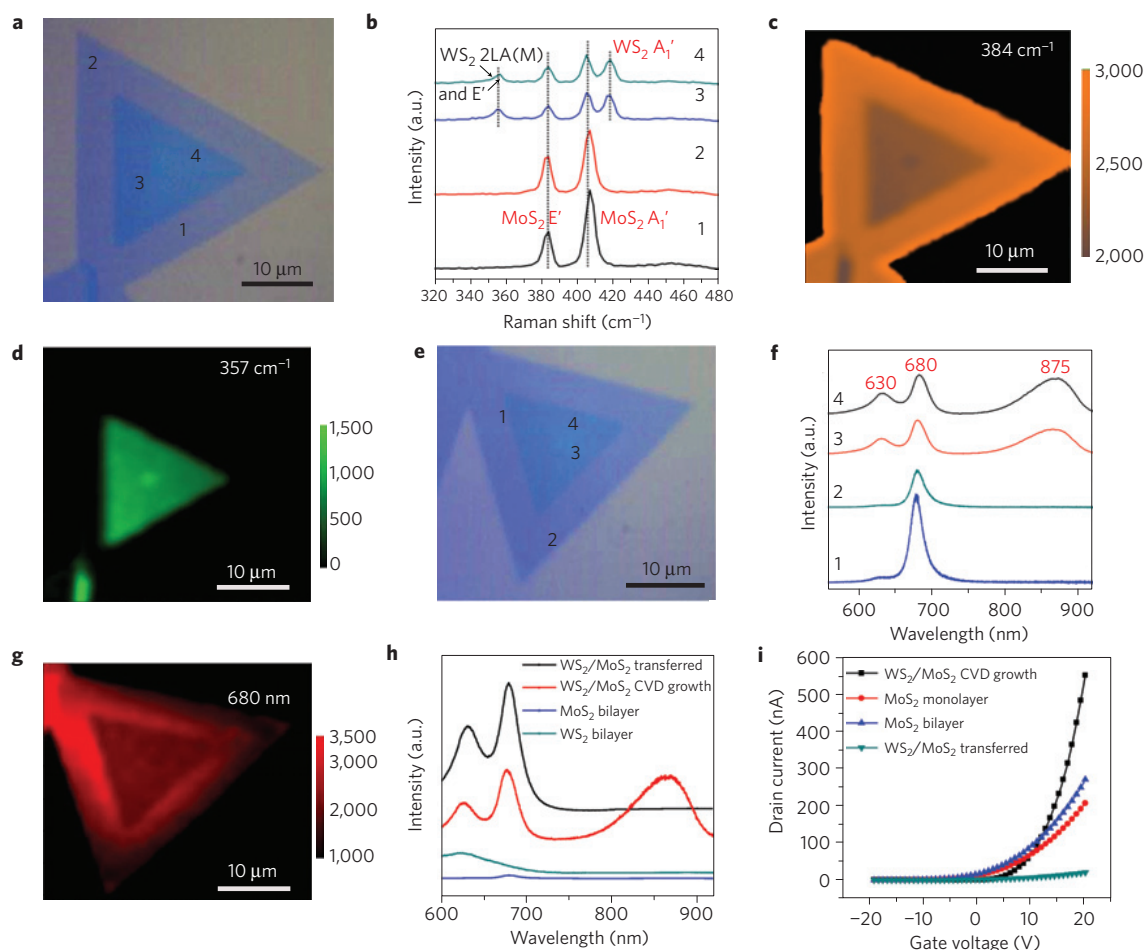

Figure 3 | Raman and PL characterization of the WS$_2$/MoS$_2$ vertical heterostructure. a, Optical image of a WS$_2$/MoS$_2$ heterostructure used for Raman characterization. **b**, Raman spectra taken from the four points marked in **a**, showing that the monolayer region is pure MoS$_2$, whereas the double layer area is the superposition of MoS$_2$ and WS$_2$ monolayers. The dashed lines are guides to the eye showing the position of the MoS$_2$ and WS$_2$ Raman peaks. **c,d**, Raman intensity mapping at 384 cm^{-1} and 357 cm^{-1}, respectively. The lower Raman intensity at the centre of the triangle in **c** is due to the coverage of WS$_2$. **e**, Optical image of a WS$_2$/MoS$_2$ heterostructure used for PL characterization. **f**, PL Spectra taken from the four points marked in **e**, showing the characteristic MoS$_2$ PL peak at the monolayer region and three peaks at the bilayer region. **g**, PL intensity mapping at 680 nm shows localized PL enhancement around the step edge of the bilayer region. **h**, PL spectra of a CVD-grown WS$_2$/MoS$_2$ bilayer, a WS$_2$/MoS$_2$ bilayer made by mechanical transfer, and CVD-grown MoS$_2$ and WS$_2$ bilayers. All spectra were taken at the same laser intensity and plotted to the same scale. The PL peak at 875 nm is absent in the mechanically transferred bilayer sample, and the bilayer MoS$_2$ and WS$_2$ have a very weak PL response owing to their indirect bandgap. **i**, Typical plot of gating voltage versus source/drain current of a CVD-grown WS$_2$/MoS$_2$ bilayer, a mechanically transferred WS$_2$/MoS$_2$ bilayer, a MoS$_2$ bilayer and monolayer MoS$_2$ demonstrating that the CVD-grown WS$_2$/MoS$_2$ bilayer has the best performance.

W atoms is also found to substitute into the MoS$_2$ layer (Fig. 2f). However, the substitution is at a fairly low concentration (∼3%, see Supplementary Fig. 9 for details), which would have only a minimal effect on the properties of the MoS$_2$ and WS$_2$ monolayers.

Raman and PL spectroscopy were used to further characterize the vertical bilayer heterostructure. As shown in Fig. 3a,b, Raman spectra collected from the light purple area (points 1 and 2) show only the E′ (at 383.9 cm^{-1}) and A$_1'$ (at 405.3 cm^{-1}) peaks of the MoS$_2$ monolayer[8,9], confirming the bottom layer is MoS$_2$ (ref. 31). In the bilayer region (points 3 and 4 in the dark purple area), however, two additional peaks located at 418.5 cm^{-1} and 356.8 cm^{-1} are observed, which can be assigned to the A$_1'$ mode and the overlapping 2LA(M) and E′ modes, respectively, of the top WS$_2$ monolayer[6,32] (details in Supplementary Fig. 10). Raman intensity mapping using the MoS$_2$ E′ mode at 384 cm^{-1} and the WS$_2$ E′ mode at 357 cm^{-1} further demonstrate the formation of WS$_2$/MoS$_2$ bilayer stacks, as shown in Fig. 3c,d.

The PL spectra (Fig. 3f) acquired from the monolayer region (points 1 and 2 in Fig. 3e) show a strong peak only at a wavelength

of 680 nm, corresponding to the 1.82 eV direct excitonic transition energy in monolayer MoS$_2$. However, on the bilayer region (points 3 and 4), three prominent peaks are observed at wavelengths of 630 nm, 680 nm and 875 nm, corresponding to excitonic transition energies of 1.97 eV, 1.82 eV and 1.42 eV, respectively. The peaks at 630 nm (1.97 eV) and 680 nm (1.82 eV) can be attributed to the direct excitonic transition energies in the top WS$_2$ and bottom MoS$_2$ monolayers, respectively. It has been reported that the increased indirect excitonic transition in multilayer WS$_2$ and MoS$_2$ (refs 7,33) can generate small peaks at a similar lower transition energy range. The intensity of such indirect excitonic peaks, however, is more than three orders of magnitude lower than the direct excitonic peak from monolayers. The comparable intensity of the peak at 875 nm to that of its individual monolayer components observed in our bilayer sample, as shown in Fig. 3f, indicates a possible direct excitonic transition at this energy range. Such a strong direct excitonic peak at 875 nm (1.42 eV) is indeed observed for the first time in this bilayer heterostructure. This experimental observation is consistent with previous theoretical calculations, which suggest the coupling

between the WS_2 and MoS_2 layers leads to an unprecedented direct bandgap with reduced energy[25,26]. Supplementary Fig. 11 shows the PL intensity mapping at 875 nm, confirming the intensity is localized at the bilayer region. Notably, the PL signal from MoS_2 at 680 nm shows a localized enhancement near the step edges between the monolayer and bilayer regions, as shown in Fig. 3g and further illustrated by the PL intensity line profile shown in Supplementary Fig. 12. The PL enhancement is also demonstrated by analysing the PL spectra extracted from the step-edge region (point 1) and the edge of the MoS_2 monolayer (point 2 in Fig. 3e), showing almost twice the difference in intensity. This step-edge enhancement is distinctly different from the previous reported edge-enhanced[6] or homogeneous[34] PL response in monolayer TMDs, and may be caused by the interaction between the MoS_2 and WS_2 layers.

As a comparison, Raman and PL measurements were also performed on a stacked WS_2/MoS_2 heterostructure, made by the commonly-used mechanical transfer method, and on a CVD-grown MoS_2/WS_2 bilayer (Fig. 3h and Supplementary Fig. 13). Although the Raman spectra are similar to the WS_2/MoS_2 bilayer from direct growth (Supplementary Fig. 13), the additional PL peak at 875 nm, originating from an interlayer excitonic transition[25,26], is absent in the PL spectra from the mechanically transfer-stacked bilayer sample, presumably owing to contamination at the interface during the mechanical transfer of the two layers. This peak at 875 nm should also be observable in transferred layers if a contamination-free interface could be achieved. These results highlight the advantage of using our CVD method for the direct growth of crystalline heterostructures, in which layer transfers are not needed and a clean interface could be readily obtained. In addition, the 1.82 eV (680 nm) and 1.97 eV (630 nm) PL peaks observed in the stacked WS_2/MoS_2 bilayer almost vanish in a CVD-grown MoS_2 bilayer and WS_2 bilayer[7]. This observation suggests that the MoS_2 and WS_2 layers in the bilayer heterostructure, on one hand, behave as individual monolayers and, on the other hand, generate new functionalities (an additional direct bandgap) of the WS_2/MoS_2 heterostructure via interlayer coupling owing to the clean interface.

To illustrate the high quality of the CVD-grown heterostructures, we demonstrate high-mobility back-gating vertically stacked WS_2/MoS_2 field-effect transistors (FETs) (Fig. 3i and Supplementary Fig. 14). As FETs, the ON/OFF ratio is larger than 10^6, and the estimated mobility (Supplementary Information) ranges from 15 to 34 $cm^2 V^{-1} s^{-1}$—which is much higher than the average mobility of the monolayer MoS_2 (4.5 $cm^2 V^{-1} s^{-1}$)[8,9], MoS_2 bilayer (5.7 $cm^2 V^{-1} s^{-1}$) and WS_2/MoS_2 bilayer made by the transfer method (0.51 $cm^2 V^{-1} s^{-1}$)—thus suggesting that a clean interface between WS_2 and MoS_2 is crucial in achieving a high device performance. The poor FET performance WS_2/MoS_2 bilayer made by the transfer method is possibly due to the presence of unwanted species trapped between layers.

In-plane heterostructure

The lateral interface between WS_2 and MoS_2 within the in-plane connected heterostructure appears as straight lines in a triangular shape in the optical images (Fig. 1e–h), thus suggesting that the lateral epitaxy of WS_2 on the MoS_2 edge occurs preferentially along the zigzag direction. Such an assessment provides a macroscopic view of the WS_2/MoS_2 planar heterojunctions; however, the detailed atomic structure can be revealed only by high-resolution STEM Z-contrast imaging. Figure 4a shows a Z-contrast image of the lateral interface, where W atoms exhibit much higher image intensity than the Mo atoms. A series of sharp zigzag step interfaces can be easily identified along the overall-straight WS_2/MoS_2 lateral junction. An atomically sharp interface is consistently observed. Figure 4b shows another atomically sharp interface along the zigzag direction, where all atomic columns are directly visible. Careful

examination of this STEM image reveals that the WS_2 and MoS_2 domains connect seamlessly at the interface into a single hexagonal monolayer lattice and share the same crystal orientation, as demonstrated in Fig. 4b (atomic model provided in Supplementary Fig. 15). The formation of such an atomically coherent interface is a strong indication of lateral epitaxy growth in which the WS_2 monolayer grows directly from the fresh MoS_2 edges with atomic lattice coherence. Lateral epitaxy is also supported by the electron diffraction pattern (Supplementary Fig. 16). The interfacial steps most probably originate from small fluctuations of the MoS_2 growth rate at the nanometre scale, and their presence contributes to the overall roughness of the lateral WS_2/MoS_2 interface. We estimate the overall roughness of the WS_2/MoS_2 interface by the evolution of the local W concentration, integrated along individual atomic planes parallel to the overall interface, as presented in Supplementary Fig. 17. The overall roughness of the lateral interface is estimated to be ~4 unit cells over a width of 15 nm (Supplementary Figs 17 and 18), and we expect that this could be further reduced by optimizing the CVD growth conditions.

Despite the small overall roughness due to interfacial steps, each individual WS_2/MoS_2 heterojunction along the zigzag direction is found to be atomically abrupt, as shown by the high-magnification STEM Z-contrast images in Fig. 4b,c. The corresponding atomic model, obtained via atom-by-atom image quantification, clearly indicates the seamless connection and abrupt transition between the MoS_2 and WS_2 lattice within a single atomic row (Supplementary Figs 15 and 19). To the best of our knowledge, this is the first demonstration and direct visualization of an atomically abrupt lateral interface between two different 2D materials with atomic resolution. Besides the preferred zigzag interface, lateral junctions along the armchair direction are also occasionally observed in our sample, as shown in Fig. 4d and Supplementary Fig. 20. Slight inter-diffusion of transition-metal elements is often observed along such armchair interfaces, typically over a width of 1–3 unit cells (Supplementary Figs 19 and 20), presumably due to the relatively low stability of the fresh armchair MoS_2 edges during the epitaxial growth of the WS_2 layer[35]. Nevertheless, our growth produces the highest quality 2D in-plane heterostructures reported so far, with atomically coherent sharp interfaces providing an excellent platform for studying intralayer coupling effects.

The lateral WS_2/MoS_2 interface was further studied by Raman and PL spectroscopy. Figure 5a shows an optical image of the WS_2/MoS_2 in-plane heterojunction used for Raman and PL characterization. Raman spectra (Fig. 5b) and mapping (Fig. 5c) at 351 cm^{-1} (yellow) and 381 cm^{-1} (purple) both confirm the formation of an in-plane WS_2/MoS_2 heterostructure, with a triangular monolayer MoS_2 domain as the core and WS_2 being the shell layer (individual mapping is shown in Supplementary Fig. 21). Similarly, PL spectra acquired from the outer layer (point 1 in Fig. 5d) and inner layer (point 5 in Fig. 5d) show characteristic PL peaks of pristine monolayer WS_2 and MoS_2, respectively, and the PL intensity mapping using these two peaks also reveals the core–shell structure of this unique lateral heterostructure (Fig. 5f and Supplementary Fig. 22). Note that owing to the large laser spot size (~1 μm) used in our experiment, the lateral interface in the Raman and PL mappings seems slightly diffuse, and the Raman spectra from the interface area correspond to signals from both sides of the atomically abrupt heterojunction.

Even though the lateral heterostructure has been revealed by STEM imaging to have sharp interfaces with very limited inter-diffusion, the PL peak position shifts continuously across the interface from 630 nm (for WS_2) to 680 nm (for MoS_2), as shown by the spectra presented in Fig. 5d. Noticeably, the PL spectrum acquired at the interface (point 3) shows a broad and strong peak at 650 nm (1.91 eV). The observed shift in peak position and changes in peak shape cannot simply be due to a large laser spot size that
Figure 4 | Atomic structure of the lateral heterojunctions between WS$_2$ and MoS$_2$ monolayers. a,b, Atomic-resolution Z-contrast STEM images of the in-plane interface between WS$_2$ and MoS$_2$ domains. A small roughness resulting from interfacial steps can be seen in **a**. The red dashed lines highlight the atomically sharp interface along the zigzag-edge direction. The orange and pink dashed lines in **b** depict the atomic planes along the armchair and zigzag directions, respectively, indicating the WS$_2$ and MoS$_2$ domains share the same crystal orientation. **c,d**, Atomic-resolution Z-contrast images of the atomically sharp lateral interfaces along the zigzag (**c**) and armchair (**d**) directions. The atomic models on the right correspond to the structure in the highlighted regions. Scale bars: **a**, 1 nm; **b–d**, 0.5 nm.

picks up averaged information from an ∼1 μm^2 area, as illustrated by the distinct difference between the PL spectrum acquired at the interface (point 3) and the superposition of spectra from pure MoS$_2$ and pure WS$_2$ (Fig. 5e). Furthermore, PL intensity mapping at 650 nm (Fig. 5g) reveals that this strong PL response is localized at the lateral interface, and the intensity drops significantly at the intersections of these interfaces, which is consistent with the PL spectra presented in Fig. 5e. The shift of the PL peak to intermediate energies near the interface can be explained as follows. Excitons near the interface have wavefunctions that overlap the other side,

which causes a shift that gradually evolves to the excitonic peak on the other side. When the laser spot is focused on the interface, it generates excitons at intermediate energies, resulting in the observed broad peak between the two pristine excitonic peaks. This observed peak contains contributions from excitons that have an electron predominantly on one side and a hole predominantly on the other side (such excitons also have an intermediate energy, as discussed in Supplementary Figs 23 and 24).

To further assess the localized interfacial effect, we acquired a high-resolution PL microscope image from the heterostructure, as
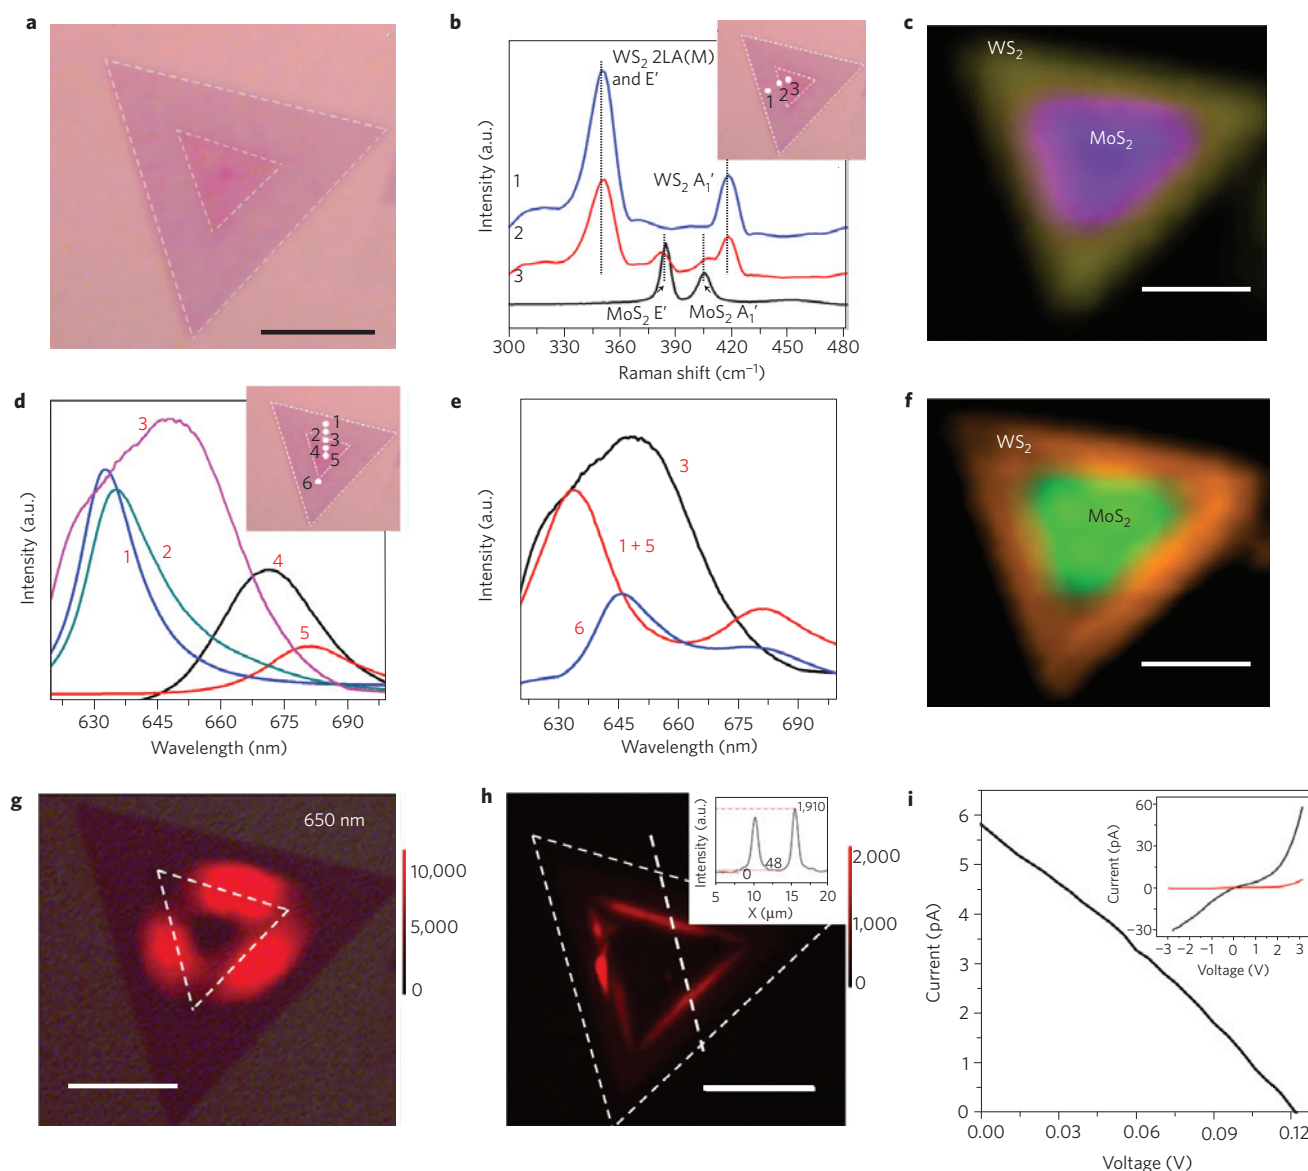

Figure 5 | Raman and PL characterizations of in-plane WS$_2$/MoS$_2$ heterojunction. a, Optical microscopy image of a triangular in-plane WS$_2$/MoS$_2$ heterojunction. **b**, Raman spectra taken from the points marked by 1–3 in the inset, showing characteristic WS$_2$ (point 1) and MoS$_2$ (point 3) peaks in the outer and inner triangles, respectively, and their superposition at the interface region (point 2). The dashed lines are guides to the eye showing the position of the MoS$_2$ and WS$_2$ Raman peaks. **c**, Combined Raman intensity mapping at 351 cm^{-1} (yellow) and 381 cm^{-1} (purple), showing the core–shell structure with WS$_2$ as the shell and MoS$_2$ as the core. **d**, PL spectra of the points marked by 1–5 in the inset. The peak positions for spectra 1 and 5 are 630 nm and 680 nm, respectively, indicating pure WS$_2$ and pure MoS$_2$. The PL peak shifts on approaching the interface (points 2 and 4). At the interface (point 3), a stronger broad peak at 650 nm shows up. **e**, PL spectra at the interface (point 3), at the intersection of interface (point 6) and the superposition of spectra from pure MoS$_2$ (point 5) and pure WS$_2$ (point 1). **f**, Combined PL intensity mapping at 630 nm (orange) and 680 nm (green). **g**, PL intensity mapping at 650 nm, showing a localized response around the interface. The optical image with the interface highlighted is overlaid in **g**. **h**, PL microscope image of the same region in **g** in false colour, showing strong localized PL enhancement at the interface. Inset is the corresponding intensity profile along the marked dashed line, and the corresponding intensities of the interface (1,910), pristine MoS$_2$ (48) and background (0) are marked. **i**, Photovoltaic effect of the in-plane heterojunction. Inset is the typical I–V curve of the junction with (black) and without (red) illumination, showing the p–n junction behaviour. Scale bars in **a,c,f–h**, 10 μm.

shown in Fig. 5h. Strong (around 40 times enhancement compared to the pristine MoS$_2$ or WS$_2$) and highly localized (within 250 nm of FWHM) PL enhancement is clearly shown along the lateral interfaces. In comparison, the PL signals from pristine MoS$_2$ or WS$_2$ areas are close to the background level from the SiO$_2$/Si substrate. Such localized interfacial excitonic enhancement may be due to the strong built-in electric field at the atomically sharp interface originating from the type II band alignment, as confirmed by density functional theory (DFT) calculations (Supplementary Fig. 25). The

interface serves as an enhanced excitonic recombination centre, where the strong built-in electric field breaks the coherence of the electron–hole pairs generated in the vicinity of the interface, leading to their preferential recombination at the interface. In contrast, in the areas of 'bulk' monolayer MoS$_2$ or WS$_2$, radiative recombination of excitons may be suppressed by non-radiative channels.

The lateral WS$_2$/MoS$_2$ heterostructures are further demonstrated to serve as intrinsic monolayer p–n junctions (Fig. 5i and Supplementary Fig. 26) without external electrical tuning. The

forward bias current is two orders of magnitude higher than the reverse current, implying a good rectification character, unique in 2D electronics. Furthermore, under illumination, the lateral heterostructure shows a clear photovoltaic effect, which is also solid evidence for the existence of a p–n junction (Fig. 5i). Such a photovoltaic effect is consistent with the band alignment calculations presented in Supplementary Fig. 25. An open-loop voltage of 0.12 V and close-loop current of 5.7 pA is obtained. This is the first time that the p–n junction and photovoltaic effect have been achieved in monolayer materials without external gating[15–17].

In summary, we have demonstrated the growth of high-quality vertical and lateral WS_2/MoS_2 heterostructures with clean and atomically sharp interfaces. The well-defined, sharp and clean interfaces in these heterostructures allow us to explore new and controlled designs for 2D materials. The specific orientation relationships and ordering between the individual monolayer domains can lead to specific interface electronic properties that cannot be obtained in randomly assembled van der Waals heteromaterials. Such scalable methods to grow engineered 2D heterostructures could lead to interesting applications, such as vertically stacked FET devices and planar monolayer devices. Combining both vertical and lateral 2D heterostructures opens up the possibility to create unprecedented architectures using 2D atomic layer building blocks.

Author contributions

Y.G., J.L. and X.W. contributed equally to this work. Y.G. designed the growth procedures and carried out part of the characterization. Y.G., X.W. and G.Y. worked on the growth. W.Z. and J.L. carried out STEM experiments. G.S. and S.L. made the FET devices and carried out the electrical measurement. Z.L. performed part of the Raman and PL characterization. H.T., X.Z. and J.L. carried out DFT calculations. Y.G., J.L., X.W., W.Z., Z.L., G.S., S.L., M.T., H.T. and P.M.A. analysed the results and co-wrote the paper. All authors participated in discussions.

Additional information

Supplementary information is available in the online version of the paper. Reprints and permissions information is available online at www.nature.com/reprints.
Correspondence and requests for materials should be addressed to W.Z. or P.M.A.
